### Chapter 5

Names, Bindings, and Scopes

# Chapter 5 Topics

- Introduction
- Names
- Variables
- The Concept of Binding
- Scope
- Scope and Lifetime
- Referencing Environments
- Named Constants

#### Introduction

- Imperative languages are abstractions of von Neumann architecture
  - Memory
  - Processor
- Variables are characterized by attributes
  - To design a type, must consider scope, lifetime, type checking, initialization, and type compatibility

#### **Names**

- Design issues for names:
  - Are names case sensitive?
  - Are special words reserved words or keywords?

#### Length

- If too short, they cannot be connotative
- Language examples:
  - FORTRAN 95: maximum of 31
  - C99: no limit but only the first 63 are significant; also, external names are limited to a maximum of 31
  - · C#, Ada, and Java: no limit, and all are significant
  - C++: no limit, but implementers often impose one

#### Special characters

- PHP: all variable names must begin with dollar signs
- Perl: all variable names begin with special characters, which specify the variable's type
- Ruby: variable names that begin with @ are instance variables; those that begin with @ are class variables

#### Case sensitivity

- Disadvantage: readability (names that look alike are different)
  - Names in the C-based languages are case sensitive
  - Names in others are not
  - Worse in C++, Java, and C# because predefined names are mixed case (e.g.

IndexOutOfBoundsException)

#### Special words

- An aid to readability; used to delimit or separate statement clauses
  - A keyword is a word that is special only in certain contexts, e.g., in Fortran
    - Real VarName (Real is a data type followed with a name, therefore Real is a keyword)
    - Real = 3.4 (Real is a variable)
- A reserved word is a special word that cannot be used as a user-defined name
- Potential problem with reserved words: If there are too many, many collisions occur (e.g., COBOL has 300 reserved words!)

#### **Variables**

- A variable is an abstraction of a memory cell
- Variables can be characterized as a sextuple of attributes:
  - Name
  - Address
  - Value
  - Type
  - Lifetime
  - Scope

#### Variables Attributes

- Name not all variables have them
- Address the memory address with which it is associated
  - A variable may have different addresses at different times during execution
  - A variable may have different addresses at different places in a program
  - If two variable names can be used to access the same memory location, they are called aliases
  - Aliases are created via pointers, reference variables, C and C++ unions
  - Aliases are harmful to readability (program readers must remember all of them)

### Variables Attributes (continued)

- Type determines the range of values of variables and the set of operations that are defined for values of that type; in the case of floating point, type also determines the precision
- Value the contents of the location with which the variable is associated
  - The I-value of a variable is its address.
  - The r-value of a variable is its value
- Abstract memory cell the physical cell or collection of cells associated with a variable

# The Concept of Binding

A binding is an association between an entity and an attribute, such as between a variable and its type or value, or between an operation and a symbol

 Binding time is the time at which a binding takes place.

# Possible Binding Times

- Language design time bind operator symbols to operations
- Language implementation time— bind floating point type to a representation
- Compile time -- bind a variable to a type in C or Java
- Load time -- bind a C or C++ static
   variable to a memory cell)
- Runtime bind a nonstatic local variable to a memory cell

# Static and Dynamic Binding

- A binding is static if it first occurs before run time and remains unchanged throughout program execution.
- A binding is dynamic if it first occurs during execution or can change during execution of the program

# Type Binding

- How is a type specified?
- When does the binding take place?
- If static, the type may be specified by either an explicit or an implicit declaration

# Explicit/Implicit Declaration

- An explicit declaration is a program statement used for declaring the types of variables
- An implicit declaration is a default mechanism for specifying types of variables through default conventions, rather than declaration statements
- Fortran, BASIC, Perl, Ruby, JavaScript, and PHP provide implicit declarations (Fortran has both explicit and implicit)
  - Advantage: writability (a minor convenience)
  - Disadvantage: reliability (less trouble with Perl)

### Explicit/Implicit Declaration (continued)

- Some languages use type inferencing to determine types of variables (context)
  - C# a variable can be declared with var and an initial value. The initial value sets the type
  - Visual BASIC 9.0+, ML, Haskell, F#, and Go use type inferencing. The context of the appearance of a variable determines its type

### Dynamic Type Binding

- Dynamic Type Binding (JavaScript, Python, Ruby, PHP, and C# (limited))
- Specified through an assignment statement e.g., JavaScript

```
list = [2, 4.33, 6, 8];
list = 17.3;
```

- Advantage: flexibility (generic program units)
- Disadvantages:
  - High cost (dynamic type checking and interpretation)
  - Type error detection by the compiler is difficult

#### Variable Attributes (continued)

- Storage Bindings & Lifetime
  - Allocation getting a cell from some pool of available cells
  - Deallocation putting a cell back into the pool
- The lifetime of a variable is the time during which it is bound to a particular memory cell

- Static—bound to memory cells before execution begins and remains bound to the same memory cell throughout execution, e.g., C and C++ static variables in functions
  - Advantages: efficiency (direct addressing), history-sensitive subprogram support
  - Disadvantage: lack of flexibility (no recursion)

- Stack-dynamic--Storage bindings are created for variables when their declaration statements are elaborated.
  - (A declaration is elaborated when the executable code associated with it is executed)
- If scalar, all attributes except address are statically bound
  - local variables in C subprograms (not declared static) and Java methods
- Advantage: allows recursion; conserves storage
- Disadvantages:
  - Overhead of allocation and deallocation
  - Subprograms cannot be history sensitive
  - Inefficient references (indirect addressing)

- Explicit heap-dynamic Allocated and deallocated by explicit directives, specified by the programmer, which take effect during execution
- Referenced only through pointers or references,
   e.g. dynamic objects in C++ (via new and delete),
   all objects in Java
- Advantage: provides for dynamic storage management
- Disadvantage: inefficient and unreliable

- Implicit heap-dynamic—Allocation and deallocation caused by assignment statements
  - all variables in APL; all strings and arrays in Perl, JavaScript, and PHP
- Advantage: flexibility (generic code)
- Disadvantages:
  - Inefficient, because all attributes are dynamic
  - Loss of error detection

### Variable Attributes: Scope

- The scope of a variable is the range of statements over which it is visible
- The *local variables* of a program unit are those that are declared in that unit
- The nonlocal variables of a program unit are those that are visible in the unit but not declared there
- Global variables are a special category of nonlocal variables
- The scope rules of a language determine how references to names are associated with variables

#### Static Scope

- Based on program text
- To connect a name reference to a variable, you (or the compiler) must find the declaration
- Search process: search declarations, first locally, then in increasingly larger enclosing scopes, until one is found for the given name
- Enclosing static scopes (to a specific scope) are called its static ancestors; the nearest static ancestor is called a static parent
- Some languages allow nested subprogram definitions, which create nested static scopes (e.g., Ada, JavaScript, Common LISP, Scheme, Fortran 2003+, F#, and Python)

# Scope (continued)

- Variables can be hidden from a unit by having a "closer" variable with the same name
- Ada allows access to these "hidden" variables
  - E.g., unit.name

#### **Blocks**

- A method of creating static scopes inside program units—from ALGOL 60
- Example in C:

```
void sub() {
  int count;
  while (...) {
   int count;
   count++;
   ...
  }
  ...
}
```

- Note: legal in C and C++, but not in Java and C# - too error-prone

#### **Declaration Order**

- C99, C++, Java, and C# allow variable declarations to appear anywhere a statement can appear
  - In C99, C++, and Java, the scope of all local variables is from the declaration to the end of the block
  - In C#, the scope of any variable declared in a block is the whole block, regardless of the position of the declaration in the block
    - However, a variable still must be declared before it can be used

#### The LET Construct

- Most functional languages include some form of let construct
- A let construct has two parts
  - The first part binds names to values
  - The second part uses the names defined in the first part
- In Scheme:

```
(LET (
    (name<sub>1</sub> expression<sub>1</sub>)
    ...
    (name<sub>n</sub> expression<sub>n</sub>)
)
```

#### The LET Construct (continued)

In ML:

```
let
  val name<sub>1</sub> = expression<sub>1</sub>
  ...
  val name<sub>n</sub> = expression<sub>n</sub>
in
  expression
end;
```

- In F#:
  - First part: 1et left\_side = expression
  - (left\_side is either a name or a tuple pattern)
  - All that follows is the second part

#### Declaration Order (continued)

- In C++, Java, and C#, variables can be declared in for statements
  - The scope of such variables is restricted to the for construct

### Global Scope

- C, C++, PHP, and Python support a program structure that consists of a sequence of function definitions in a file
  - These languages allow variable declarations to appear outside function definitions
- C and C++have both declarations (just attributes) and definitions (attributes and storage)
  - A declaration outside a function definition specifies that it is defined in another file

### Global Scope (continued)

#### PHP

- Programs are embedded in HTML markup documents, in any number of fragments, some statements and some function definitions
- The scope of a variable (implicitly) declared in a function is local to the function
- The scope of a variable implicitly declared outside functions is from the declaration to the end of the program, but skips over any intervening functions
  - Global variables can be accessed in a function through the \$GLOBALS array or by declaring it global

### Global Scope (continued)

#### Python

A global variable can be referenced in functions,
 but can be assigned in a function only if it has
 been declared to be global in the function

#### **Evaluation of Static Scoping**

- Works well in many situations
- Problems:
  - In most cases, too much access is possible
  - As a program evolves, the initial structure is destroyed and local variables often become global; subprograms also gravitate toward become global, rather than nested

#### Dynamic Scope

- Based on calling sequences of program units, not their textual layout (temporal versus spatial)
- References to variables are connected to declarations by searching back through the chain of subprogram calls that forced execution to this point

# Scope Example

```
function big() {
  function sub1()
  var x = 7;
  function sub2() {
  var y = x;
  }
  var x = 3;
}
```

big calls sub1 sub1 calls sub2 uses x

- Static scoping
  - Reference to x in sub2 is to big's x
- Dynamic scoping
  - Reference to x in sub2 is to sub1's x

# Scope Example

- Evaluation of Dynamic Scoping:
  - Advantage: convenience
  - Disadvantages:
    - 1. While a subprogram is executing, its variables are visible to all subprograms it calls
    - 2. Impossible to statically type check
    - 3. Poor readability— it is not possible to statically determine the type of a variable

### Scope and Lifetime

- Scope and lifetime are sometimes closely related, but are different concepts
- Consider a static variable in a C or C++ function

### Referencing Environments

- The referencing environment of a statement is the collection of all names that are visible in the statement
- In a static-scoped language, it is the local variables plus all of the visible variables in all of the enclosing scopes
- A subprogram is active if its execution has begun but has not yet terminated
- In a dynamic-scoped language, the referencing environment is the local variables plus all visible variables in all active subprograms

#### **Named Constants**

- A named constant is a variable that is bound to a value only when it is bound to storage
- Advantages: readability and modifiability
- Used to parameterize programs
- The binding of values to named constants can be either static (called manifest constants) or dynamic
- Languages:
  - Ada, C++, and Java: expressions of any kind, dynamically bound
  - C# has two kinds, readonly and const
    - the values of const named constants are bound at compile time
    - The values of readonly named constants are dynamically bound

### Summary

- Case sensitivity and the relationship of names to special words represent design issues of names
- Variables are characterized by the sextuples: name, address, value, type, lifetime, scope
- Binding is the association of attributes with program entities
- Scalar variables are categorized as: static, stack dynamic, explicit heap dynamic, implicit heap dynamic
- Strong typing means detecting all type errors
